Simulation of Nitrogen Balance in Rice–Wheat Systems of the Indo-Gangetic Plains

H. Pathak, C. Li, R. Wassmann, and J. K. Ladha*

ABSTRACT

Crop growth simulation models provide a means to quantify the effects of climate, soil, and management on crop growth and biogeochemical processes in soil. The Denitrification and Decomposition (DNDC) model was evaluated for its ability to simulate N dynamics and balance in the rice (Oryza sativa L.)–wheat (Triticum aestivum L.) cropping systems in the Indo-Gangetic Plains with various N and water management practices. The observed crop yield, N uptake, and losses of N were in agreement with the values predicted by the model. In the rice–wheat systems, current annual inputs of N through fertilizer, manure, biological fixation, atmospheric deposition, and irrigation were 98, 37, 17, 8, and 7 kg N ha$^{-1}$, respectively, while outputs through uptake, volatilization, leaching, and denitrification were 175, 14, 12, and 4 kg N ha$^{-1}$, respectively. The northwestern transects of the Indo-Gangetic Plains (Punjab and Haryana) showed greater yields and N uptake because of a higher amount of N use and more favorable climatic conditions than those in the eastern transects (Uttar Pradesh, Bihar, and West Bengal). Volatilization was the dominant N loss mechanism in Punjab and West Bengal while NO$_3$ leaching was dominant in Bihar, Uttar Pradesh, and West Bengal. The simulated balance of N was negative in all the states. The largest depletion of soil N was estimated in Bihar, followed by Uttar Pradesh, Haryana, Punjab, and West Bengal. The study suggests that better N management is required to arrest the depletion of soil N.

Rice and wheat are the two most important cereals for food world security. The rice–wheat production system occupies 21 million ha of cultivated land in the Asian subtropics (Dawe et al., 2003). In South Asia, the system occupies about 13 million ha, extending across the Indo-Gangetic floodplain (IGP) into the Himalayan foothills. The rice–wheat production system provides staple grain for more than 400 million people. During the Green Revolution era in the 1960s, production increases resulted from increases in both rice–wheat area and system productivity. But little additional land is available now and traditional farmlands are increasingly lost to urbanization. In addition, since most of the land is already double- and even triple-cropped, increasing cropping intensity is not a possible option for increasing production. Therefore, future demand for food will have to be met mainly through increases in production per unit of harvested area (Ladha et al., 2003).

In the rice–wheat systems, rice is grown in the summer months (June–October) under monsoon climatic condi-

Abbreviations: DNDC, denitrification and decomposition model; FYM, farmyard manure; GIS, geographic information systems; IGP, Indo-Gangetic Plains; SOC, soil organic carbon.
The main loss pathways are (i) leaching, predominantly NO$_3^-$; (ii) denitrification, resulting in emissions of N$_2$O, NO, and N$_2$ gases; and (iii) NH$_3$ volatilization. Efficient use of N fertilizer is one of the keys for obtaining a higher economic crop yield, increasing the use efficiency, and reducing various losses. It is of great importance, therefore, to optimize N management in crops because not only the continuous increase in fertilizer prices but also environmental pollution (Ladha et al., 2005). The prerequisite of such a management system is to quantify the dynamics and losses of N at field, farm, and regional scales.

The 20th century witnessed an emergence of new technologies. Computer-based simulation modeling, decision support systems, GIS (geographic information systems), and management information systems predominate for solving the problems that agriculture faces today. During the last four decades, several simulation models have been developed and are now in use. Simulation models have previously been applied to provide recommendations for adequate nutrient supply for both optimal crop growth and minimal losses in Indian rice production, such as Thiyagarajan et al. (1997) using ORYZA, Aggarwal et al. (2006) using InfoCrop, and Pathak et al. (2004) using the Crop Estimation through Resource and Environment Synthesis (CERES)-Rice models. Simulation of the N budget, however, including the processes of mineralization, immobilization, nitrification, NH$_3$ volatilization, and denitrification, requires more comprehensive soil–plant models that only recently became available. The ability of the models to include C and N cycling, such as CENTURY (Parton, 1996), CERES (Ritchie et al., 1998), DNDC (Li, 2000), and InfoCrop (Aggarwal et al., 2006), has generated intense interest in using them to project future outcomes of management scenarios for key environmental areas such as N losses. But these models are not yet at a stage where their predictive ability is satisfactory. Moreover, the models have hardly been used in tropical regions. The objectives of our study were to: (i) evaluate the DNDC model for its ability to simulate yield and N balances with various N and water management practices in the rice–wheat cropping system, and (ii) upscale the N balances to the rice–wheat cropping systems of the IGP.

**MATERIALS AND METHODS**

**Description of the Denitrification–Decomposition Model**

The DNDC model (Li, 2000) is a generic model of C and N biogeochemistry in agricultural ecosystems. In the model, SOC (soil organic C) resides in four major pools: plant residue (i.e., litter), microbial biomass, humads (or active humus), and passive humus. Each pool consists of two or three subpools with different specific decomposition rates. The model simulates C and N cycling in agroecosystems at a daily or subdaily time step. It consists of six interacting submodels: soil climate, plant growth, decomposition, nitrification, denitrification, and fermentation (Li et al., 1997). The soil climate submodel simulates soil temperature and moisture profiles based on soil physical properties, weather, and plant water use. The plant growth submodel calculates water and N uptake by vegetation, root respiration and plant growth, and partitioning of biomass into grain, stalk, and roots. Biomass partitioning is determined by the physiological parameters stored in the crop library files. For the empirical module, the fractions of grain, leaf plus stem, and root remain constant although the total biomass can vary.

The decomposition submodel simulates decomposition and CO$_2$ production by soil microbes and NH$_3$ volatilization. The nitrification submodel tracks growth of nitrifiers and turnover of NH$_4^+$ to NO$_3^-$. The denitrification submodel simulates denitrification and the production of NO, N$_2$O, and N$_2$, whereas the fermentation submodel quantifies CH$_4$ production, oxidation, and transport.

**Modeling Soil Nitrogen Dynamics**

The DNDC model simulates soil N dynamics by tracking several biogeochemical processes: decomposition, ammonification, NH$_4^+$—NH$_3$ equilibrium, microbial assimilation, plant uptake (grain plus straw), NH$_3$ volatilization, nitrification, and denitrification (Li et al., 1992; Li, 2000). Nitrogen through inorganic fertilizer and manure is added as an input to the model. The contribution of N due to atmospheric deposition is calculated from the data on daily rainfall and its N content. Similarly, the N contribution of irrigation water is calculated from the data on irrigation provided as inputs to the model. Addition of N through biological fixation is empirically calculated using a crop-dependent coefficient. In the DNDC, when fresh organic matter is incorporated in the soils, it is partitioned into different pools of soil organic matter, which are of different quality (i.e., C/N ratio) and hence different specific decomposition rates. Litter will be first assimilated into soil microbial biomass, which requires free NH$_4^+$ or NO$_3^-$ ions from the soil because of the difference in the C/N ratio between the microbes and litter. Once the microbes die, their biomass will turn into humus. Active humus can be further transformed into passive humus through microbial activity. During the decomposition processes, a fraction of organic N is redistributed into the soil organic matter pools, and another part is turned into NH$_4^+$ through ammonification. The free NH$_4^+$ ions dissolved in the soil liquid phase can be absorbed by the plant roots, adsorbed by clay, or oxidized to NO$_3^-$ by the nitrifiers. Driven by crop demand for N, NH$_4^+$ is absorbed by the crop with the same opportunity as NO$_3^-$.

The adsorption and desorption of NH$_4^+$ are controlled by soil cation exchange capacity and NH$_4^+$ concentration. The DNDC uses the Langmuir equation to quantify NH$_4^+$ adsorption–desorption.
Oxidation of NH$_4^+$ is calculated with a nitrification routine in DNDC. When the concentration of free NH$_4^+$ decreases in the soil liquid phase, the NH$_4^+$ ions adsorbed on the clay surfaces are gradually released into the soil water, driven by the isotherm equilibrium.

The model simulates nitrification by tracking nitrifier activity and the NH$_4^+$ concentration in the soil as influenced by environmental factors (soil temperature, moisture, and pH; Martin et al., 1998). Growth and death rates of NH$_4^+$ oxidizers are calculated based on DOC (dissolved organic C) concentration, temperature, and moisture.

Denitrification, that is, a sequential reduction of NO$_3^-$ to N$_2$, driven by denitrifying bacteria under anaerobic conditions, is controlled by soil moisture and redox potential (Stevens et al., 1998), temperature (Stanford et al., 1975), pH (Ashby et al., 1998), and substrate (e.g., DOC, NO$_3$, NO$_2$, NO, and N$_2$O) concentrations. The DNDC model simulates relative growth rates of NO$_3$, NO$_2$, NO, and N$_2$O denitrifiers based on soil redox potential, concentrations of DOC, and N oxides. An “anaerobic balloon” scheme is used in the model to divide the soil matrix into aerobic and anaerobic parts. Tracking O$_2$ diffusion and consumption in the soil profile, DNDC simulates swelling and shrinking of the “anaerobic balloon.” Only the substrates allocated in the anaerobic part are involved in denitrification. Since denitrification is a typical sequential reaction, the basic laws of sequential chemical kinetic reactions are followed to calculate NO, N$_2$O, and N$_2$ fluxes. As an intermediate of the reactions, NO or N$_2$O flux is determined by the rates of their production, consumption, and escape from the system. Diffusion rates of NO and N$_2$O are calculated as a function of soil porosity, moisture, temperature, and clay content (Li, 2000).

The model calculates NH$_3$ concentration in the soil liquid phase based on NH$_4^+$ and OH$^-$ concentrations. The concentration of NH$_4^+$ in the soil profile is simulated by the decomposition submodel, which calculates turnover rates of soil organic matter (Li et al., 1992). The concentration of OH$^-$ is determined by soil pH and temperature based on Stumm and Morgan (1981, p. 418–503). The concentration of NH$_4$ in the soil gas phase is proportional to the NH$_3$ concentration in the liquid phase as well as soil temperature (Sutton et al., 1993). It is assumed that the daily emitted fraction of the gas-phase NH$_3$ is related to the soil air-filled porosity and clay content because of their effects on NH$_3$ gas diffusion (Li, 2000).

To predict soil N leaching, a process-based model must be capable of simulating both water movement and N transformation in soils. The model calculates soil moisture and water flow by tracking precipitation, plant interception, ponding water, bypass flow, infiltration, transpiration, and evaporation (Li et al., 1992). The decomposition, nitrification, and denitrification submodels contain a relatively complete suite of N transformation reactions, including mineralization, ammonification, nitrification, NH$_3$–NH$_4$ equilibrium, NH$_3$ volatilization, and denitrification.

### Modeling Soil Water Movement

In the DNDC, water movement is simulated using the processes of surface runoff, infiltration, gravitational and matric redistribution, evaporation, and transpiration based on Ritchie et al. (1988). Water available for infiltration includes rainfall, irrigation, snow melt, and surface storage. Water will infiltrate into the soil profile layer by layer until all the water on the surface is depleted or the infiltration is limited by a frozen layer or a water-restricting layer in the soil profile. In the latter two cases, water will remain in surface storage and a fixed fraction (0.5 as the default value based on Ritchie et al. [1988]) of the water above field capacity will drain every day. Transpiration and evaporation are simulated in the DNDC as the two major pathways for water loss from soil into the atmosphere. Potential evapotranspiration is estimated based on the Priestly and Taylor (1972) approach using solar radiation and temperature (Ritchie et al., 1988). Potential evapotranspiration is separated into potential evaporation and potential transpiration based on leaf area index. Potential transpiration is determined by crop water demand, which is calculated based on a daily increment of crop biomass and water requirement index (grams of water per gram dry matter). Potential evaporation is the difference between potential evapotranspiration and potential transpiration.

During a flooding period, the entire soil profile is saturated and water drainage is estimated based on the saturated hydraulic conductivity of soil. Supported with other hydraulic features existing in the DNDC, water content in each layer is calculated at an hourly time step. The gradient between water content and field capacity in each layer drives the water flow from layer to layer. Water flow from the bottom of the soil profile at the 0.5-m depth is regarded as drainage flow.

### Model Evaluation

Data generated in field experiments on the rice–wheat cropping system conducted in New Delhi (Pathak et al., 2002) and Modipuram (Shukla et al., 2004) in northwest India were used to evaluate the model. Apart from these experiments, data from some other experiments (Sachdev et al., 2000; Banerjee et al., 2002) conducted in New Delhi were also used.

New Delhi is situated at 28.40 N and 77.12 E, at an altitude of 228 m. The climate is subtropical semiarid, with average annual rainfall of 750 mm, about 80% of which occurs from June to September. The mean maximum and minimum temperatures from July to October (rice or kharif season) are 35 and 18°C, and from November to April (wheat or rabi season) are 22.6 and 6.7°C, respectively. The alluvial soil of the experimental site was a Typic Ustochrept, loamy sand in texture (210 g clay kg$^{-1}$, 330 g silt kg$^{-1}$, and 460 g sand kg$^{-1}$), with a bulk density of 1.36 g cm$^{-3}$, pH (1:2 soil/water) of 8.1, electrical conductivity of 0.48 dS m$^{-1}$, cation exchange capacity of 7.3 cmol kg$^{-1}$, and organic C, total N, Olsen P, and NH$_4$OAc-extractable K contents of 4.5, 0.30, 0.007, and 0.13 g kg$^{-1}$, respectively (Pathak et al., 2002).

Modipuram is located at 29.44 N, 77.46 E, at an altitude of 237 m, in Uttar Pradesh (Shukla et al., 2004). The climate of the region is semiarid subtropical, with dry, hot summers and cold winters. The average annual rainfall is 810 mm, 75% of which is received during July to September. Mean maximum and minimum temperatures are 34.0 and 24.1°C during the rice season (July–October) and 26.9 and 10.1°C during the wheat (November–April) season. The soil of the experimental sites was a Typic Ustochrept (Sobhapur sandy loam), alkaline in reaction (pH 8.2), sandy loam in texture (160 g clay kg$^{-1}$, 190 g silt kg$^{-1}$, and 630 g sand kg$^{-1}$ soil), very deep (>2 m), of Gangetic alluvial origin, well drained, and containing organic C, total N, Olsen P, and NH$_4$OAc-extractable K contents of 8.3, 0.80, 0.025, and 0.31 g kg$^{-1}$, respectively.

The genetic coefficients for the rice and wheat cultivars, used as model inputs to describe crop phenology in response to temperature and photoperiod, were estimated by adjusting the coefficients until close matches were achieved between simulated and observed phenology and yield. The total thermal time requirements (above a base temperature of 10°C) for rice and wheat cultivars were calculated to be 2250 and 1200 degree days, respectively. Rate constants of rice crop development in the vegetative and reproductive stages were 0.015 and
0.044 d\(^{-1}\), respectively, while for the wheat crop the values were 0.04 and 0.026 d\(^{-1}\), respectively.

**Sensitivity Analyses**

Sensitivity of the model to changes in the amount and source of N fertilizer and irrigation for yield and N dynamics was analyzed using the baseline data (weather, soil, cultivar, location, and other inputs) of the crop year 1999–2000 in New Delhi. The rice crop was transplanted on 15 July and harvested on 25 Oct. 1999, while wheat crop was sown on 25 Nov. 1999 and harvested on 25 Mar. 2000. The simulation was started on 1 Jan. 1999 and ended on 31 Dec. 2000.

**Upscaling Nitrogen Balances from Rice–Wheat Systems in the Indo-Gangetic Plains**

The approach for upscaling N balances using the DNDC model and GIS is depicted in Fig. 2. The required input parameters of the DNDC model—consisting of daily meteorological data (maximum and minimum air temperatures, precipitation, and solar radiation), soil properties (SOC, clay contents, pH, and bulk density), field area under different rice–wheat systems, and fertilizer and manure use—were compiled in a GIS database. The IGP is spread out across several states and the states are further divided into administrative boundaries called districts. Since many of the statistical data were district based, the district was chosen as the basic geographic unit of the database to maintain the maximum accuracy of the original datasets. The meteorological data were obtained from the National Climatic Data Center in the USA, and consisted of daily records of more than 20 climatic stations across the IGP. Soil properties were compiled from the National Bureau of Soil Survey and Land Use Planning (1998) and Velayutham and Bhattacharya (2000). Field area per district under rice–wheat cropping systems was compiled from published data (Yadav and Subba Rao, 2001, p. 96). Data on N and manure use in rice and wheat in different states were collected from the Fertilizer Association of India (2003) and Ministry of Agriculture and Cooperation (2000). As data on irrigation water use in rice–wheat systems were not available, simulation was done for continuous flooding for rice and five irrigations for wheat based on the common on-farm practices of the region. Nitrogen was applied as urea, broadcast in three splits (½ at 1 d after transplanting [DAT], ⅔ at 30 DAT, and ⅓ at 55 DAT in rice and ½ at 1 d after sowing [DAS], ⅔ at 20 DAS, and ⅓ at 45 DAS in wheat). For both systems, the field was plowed three times with a moldboard plow before rice transplanting and wheat sowing. Rice was transplanted on 15 July and wheat was sown on 25 November. The model calculated annual yield, uptake in grain plus straw, and losses of N through NH\(_3\) volatilization, leaching, and denitrification for two scenarios: (i) low SOC and (ii) high SOC. The scenario for minimum losses includes the minimum values of SOC, pH, and bulk density and the maximum value of clay content of the soil, whereas the scenario for maximum emission includes the maximum values of SOC, pH, and bulk density and the minimum value of clay content of the soil. The average values of the N budget of these two scenarios are reported here. In the IGP, the farmers remove both grain and straw of rice and wheat at harvest; however, in the upper IGP (Punjab, Haryana and western Uttar Pradesh) rice straw is burnt in the field before sowing wheat. Burning of straw results in the loss of almost the entire amount of N to the atmosphere (Dobermann and Fairhurst, 2000). Thus addition of N through crop residues has not been taken into consideration in this study.

**RESULTS AND DISCUSSION**

**Performance of the Model**

Predicted grain yields agreed well with observed yields in New Delhi and Modipuram for rice and wheat.

† From Pathak et al. (2002, 2003b), Shukla et al. (2004), Banerjee et al. (2002), Aulakh et al. (2001), and Bijay-Singh et al. (2002).

The model also simulated uptake of N by rice and wheat satisfactorily. The model predicted total annual losses of N from leaching, NH\(_3\) volatilization, and denitrification from rice–wheat fields in northwest India similar to those observed in the experiments conducted at the New Delhi site (Banerjee et al., 2002) and various other places in the region (Aulakh et al., 2001; Aulakh and Bijay-Singh, 1997; Katyal et al., 1985, 1987; Bijay-Singh et al., 2002). Some earlier studies have shown that the leaching loss of N from soils in the IGP is 10 to 15 kg N ha\(^{-1}\) while the NH\(_3\) volatilization loss is 20 to 30 kg N ha\(^{-1}\) with application of 120 kg N ha\(^{-1}\) in rice and wheat (Katyal et al., 1987; Aulakh and Bijay-Singh, 1997; Parashar et al., 1998). On an average, denitrification losses of ~10 to 15 and 5 to 10 kg N ha\(^{-1}\) in rice and wheat, respectively, with application of 120 kg N ha\(^{-1}\) have been reported (Srivastava and Singh, 1996).

The model also simulated similar magnitude of losses of N (Table 1). The DNDC model has been widely used during the last 12 yr by many researchers in various parts of the world (Brown et al., 2002; Butterbach-Bahl et al., 2004; Cai et al., 2003; Li et al., 1992, 1997, 2001, 2004; Pathak et al., 2005; Smith et al., 2002, 2004; Sagar et al., 2004). Results showed that the DNDC was able to simulate the N fluxes from soil quite satisfactorily. The limitation of this study, however, was the availability of only a few measured data on NH\(_3\) loss, NO\(_3\) leached, and denitrification, because of which detailed comparison of the observed and simulated values has not been possible. Moreover, there is no single experiment in south Asia where all the loss measurements have been done simultaneously. Therefore, research should be performed to quantify all the components of the N budget in some selected locations in different agroecological zones.

### Sensitivity Analyses

Sensitivity of the model was analyzed for the effect of various N and water management practices on yield, N uptake, and N losses in rice and wheat in Delhi. Yield as well as N uptake of rice increased with N application up to 300 kg ha\(^{-1}\), but with small increases at rates above 180 kg ha\(^{-1}\) (Table 2). Volatilization of NH\(_3\), the major loss mechanism of N, increased as the N application rate increased. High soil pH (8.2) along with high temperature was responsible for such a high loss of N through volatilization. Leaching and denitrification losses of N remained similar at all levels of N application. In this simulation, the soil remained flooded and anaerobic conditions prevailed throughout the rice-cropping period; as a result, there was no nitrification, which requires aerobic conditions to form NO\(_3\). As no NO\(_3\) was formed, loss of N from leaching and denitrification was limited during rice cropping.

Urea at 60 kg N ha\(^{-1}\) plus 60 kg N ha\(^{-1}\) from FYM (farmyard manure) reduced grain yield and N uptake compared with 120 kg N ha\(^{-1}\) through urea alone (Table 2). Slow mineralization of N from FYM resulted in lower N availability, which was responsible for the decrease in yield and N uptake (Pathak et al., 2002).

Water management also influenced simulated yield, N uptake, and losses of N from soil in rice (Table 2). Treatments with continuous flooding gave higher yields and N uptake than midseason drainage treatments. However, one and two midseason drainages of 10 d each increased denitrification and leaching and decreased volatilization compared with continuously flooded soil. As midseason drainage resulted in aerobic soil conditions with enhanced nitrification forming NO\(_3\), denitrification and leaching were enhanced (Aulakh et al., 1992).

Yield and N uptake of wheat increased with N application up to 300 kg ha\(^{-1}\), but with small increases at rates above 120 kg ha\(^{-1}\) (Table 3). At lower N levels (up to 60 kg N ha\(^{-1}\)), there was a similar magnitude of N loss from volatilization, leaching, and denitrification. With 120 kg N ha\(^{-1}\) and more, however, volatilization increased with N application (Table 3). Unlike in rice, leaching and denitrification losses of N were substantial at all levels of N application in wheat.

Table 2. Sensitivity analysis for effects of different rates of N application as urea and manure, and different water regimes on simulated yield, N uptake, and N losses in rice in Delhi.

† CF = continuous flooding; 1MD and 2MD = one and two midseason drainages, respectively.
‡ Plus 60 kg N ha\(^{-1}\) from farmyard manure.
Substituting 60 kg N ha\(^{-1}\) from FYM for 60 kg N ha\(^{-1}\) from urea reduced grain yield, N uptake, and losses of N by volatilization and leaching in wheat compared with the application of 120 kg N ha\(^{-1}\) through urea alone (Table 3). Slow mineralization of N from FYM, resulting in lower N availability, was responsible for such a decrease in yield, N uptake, and N losses.

### Model Applications

The model was applied to calculate N outputs through crop uptake, leaching, volatilization, and denitrification in a rice–wheat system in Delhi using the baseline data (weather, soil, cultivar, location, and other inputs) of the crop year 1999–2000 (Table 4). The treatments included N levels ranging from 120 to 360 kg N ha\(^{-1}\) in the cropping system through urea, FYM, and their combinations. The rice crop was transplanted on 15 July and harvested on 25 Oct. 1999. The wheat crop was sown on 25 Nov. 1999 and harvested on 25 Mar. 2000. The simulation was started on 1 Jan. 1999 and ended on 31 Dec. 2000.

Uptake of N varied between 87 and 259 kg N ha\(^{-1}\), with the lowest in the FYM-alone treatment and the highest with the application of 360 kg N ha\(^{-1}\) through urea. Loss of N from volatilization was substantial, ranging from 18 kg ha\(^{-1}\) in the FYM treatment to 96 kg ha\(^{-1}\) with 360 kg N through urea alone (Table 4). Loss from volatilization was greater in the treatments with N application through urea alone. In a subtropical, semiarid climate with high soil pH, loss due to NH\(_3\) volatilization is very high when N is topdressed as urea (Banerjee et al., 1992). Total leaching loss of N varied from 10 to 31 kg ha\(^{-1}\) (Table 4). Losses were similar (10 kg ha\(^{-1}\)) when 120, 240, and 240 kg N ha\(^{-1}\) was applied through urea, urea plus FYM, or FYM alone, respectively, but the application of higher amounts of urea-N increased the leaching loss. The N loss due to denitrification ranged from 14 kg ha\(^{-1}\) in the FYM treatment to 23 kg ha\(^{-1}\) in the 360 kg N ha\(^{-1}\) urea treatment.

Treatments with urea-N alone had negative balances of N ranging from 26 to 49 kg N ha\(^{-1}\), whereas the application of FYM, either in combination with urea or alone, showed a positive N balance (Table 4). Depletion of soil N in the rice–wheat cropping system was also reported by Bhandari et al. (2002) and Regmi et al. (2002) when the recommended level of N (120 kg N ha\(^{-1}\) in rice and wheat each) was applied through urea alone. In our study, a larger amount of urea application reduced the depletion of N from the soil, suggesting that the present level of N application is inadequate to arrest the depletion of soil N and that a larger amount of fertilizer N with better management to reduce N loss and improve N use efficiency is required to maintain the balance (Ladha et al., 2005). A positive N balance in the FYM treatment suggested the need to apply N through organic sources to sustain the N balance in soil under the rice–wheat cropping system.

### Upscaling Nitrogen Balances in Rice–Wheat Systems of the Indo-Gangetic Plains

#### Database of Rice–Wheat Cropping Systems and Soil

The total area under the rice–wheat system in the five states—Punjab, Haryana, Uttar Pradesh, Bihar, and West Bengal—located in the IGP is 7.55 million ha (Yadav and Subba Rao, 2001, p. 96). The largest area is in Uttar Pradesh (3.46 million ha), followed by Punjab and Bihar (Table 5). There are some other rice–wheat growing areas in India (~2.5 million ha) located outside the IGP, but these were not considered in this study.

† From Yadav and Subba Rao (2001, p. 96).
‡ From Fertilizer Association of India (2003).
¶ From Ministry of Agriculture and Cooperation (2000).

Fertilizer use is the highest in Punjab (139 kg N ha⁻¹ yr⁻¹) and it decreases gradually in the eastern part of the IGP. In Bihar and West Bengal, fertilizer use is 70 and 80 kg N ha⁻¹ yr⁻¹, respectively. Manure use also follows a similar trend, except in West Bengal, where it is the highest. Yields of rice and wheat in these states give a mirror image of N use through manure and fertilizer. Yields gradually decrease from Punjab (5019 and 4696 kg ha⁻¹ for rice and wheat, respectively) to Bihar (2310 and 2061 kg ha⁻¹ for rice and wheat, respectively) but increase in West Bengal, where a higher amount of N is used in the rice–wheat system. Favorable climatic conditions in the northwestern transects of the IGP (Punjab and Haryana) are also responsible for larger yield and N uptake than those in the eastern transects (Pathak et al., 2003a).

The spatial distribution of SOC, clay content, pH, and bulk density of soils in the rice–wheat growing regions of the IGP is presented at the district scale in Fig. 3. Being in the tropical region, with a lighter soil texture and inadequate recycling of organic matter, the SOC content of the soil is low, with a majority of soils containing SOC < 0.5% (Fig. 3a). The soils are lighter in texture, with clay content varying from 20 to 30% (Fig. 3b). A majority of the soils are alkaline (pH > 7), and some soils in the lower transect of the IGP (parts of Bihar and West Bengal) are acidic in reaction (Fig. 3c). The soils of the upper transect (Punjab and Haryana) have a higher bulk density than those from the lower transects (Fig. 3d).

**Balance of Nitrogen**

Current inputs in the rice–wheat system of the IGP ranged from 107 to 224 kg N ha⁻¹, with an average of 166 kg N ha⁻¹ (Table 6). Fertilizer was the major N input...
in most parts of the IGP. Average inputs of N through fertilizer, manure, atmospheric deposition, biological fixation, and irrigation were 98, 37, 7, 17, and 7 kg N ha$^{-1}$, respectively. Total simulated output varied between 178 and 246 kg N ha$^{-1}$ and plant uptake was the major N sink. The upper transect of the IGP showed a higher uptake because of higher N use and yield than the lower transect.

The simulated N losses from rice–wheat cropping systems through NH$_3$ volatilization, leaching, and denitrification were 5 to 31, 2 to 22, and 2 to 9 kg N ha$^{-1}$, respectively (Table 6). The spatial distribution of annual losses through volatilization, leaching, and denitrification and uptake of N in the rice–wheat systems of the IGP is shown in Fig. 4. Loss of N from volatilization was larger in Punjab and West Bengal because of a larger amount of N use through fertilizer and manure and also because of higher soil pH. A larger amount of NO$_3^-$ leaching was simulated in the lower transects because of higher rainfall. Where the upper transect receives only 650 mm of rainfall per annum, the lower transect receives $>2.5$ times (Ladha et al., 2003). Total loss of N was 16 to 62 kg N ha$^{-1}$ in the various states of the IGP. Average N loss was 30 kg N ha$^{-1}$ with average fertilizer application of 98 kg N ha$^{-1}$. Thus $\sim$30.4% of N applied through fertilizer and manure was lost from the system. Volatilization, leaching, and denitrification accounted for 15, 10, and 5 kg ha$^{-1}$ loss of N, respectively. The simulated balance of N was negative in all the states. The largest depletion of N was estimated in Bihar (71 kg N ha$^{-1}$), followed by Uttar Pradesh (58 kg N ha$^{-1}$), Haryana (45 kg N ha$^{-1}$), and Punjab.

Table 6. Simulated annual inputs, outputs, and balances of N in the rice–wheat systems for different states of the Indo-Gangetic Plain using the current farmers' practices.

Fig. 4. Annual losses through (a) NH$_3$ volatilization, (b) NO$_3^-$ leaching, (c) denitrification, and (d) uptake of N in the rice–wheat systems of the Indo-Gangetic Plain.
(22 kg N ha\(^{-1}\)), and the smallest was in West Bengal (19 kg N ha\(^{-1}\)). It has been observed that, in most of the rice–wheat long-term experiments in the IGP, the soil organic matter content has declined with time and there is a corresponding yield decline of rice and wheat under recommended NPK treatments (Duxbury et al., 2000; Yadav et al., 2000). In the major rice–wheat regions of northwestern India, the SOC has decreased from 0.5% in the 1960s to 0.2% at present (Sinha et al., 1998, p. 89). This is equivalent to a loss of 3000 kg N ha\(^{-1}\) from the entire soil profile (120 cm) during a period of 25 to 30 yr. A similar decline in organic C was evidenced in the Pakistan’s Punjab (Ali and Byerlee, 2000). During 1971 to 1974, SOC was 1.02% and decreased to 0.59% in 1985 to 1994, indicating a loss of 4000 kg N ha\(^{-1}\) from the soil profile during the period of 15 yr. In our simulation, the average loss was 39 kg N ha\(^{-1}\) yr\(^{-1}\) (Table 6). The loss was high in Uttar Pradesh and Bihar. In these states, flood and runoff contribute some amount of N annually. But quantification of this contribution is beyond the scope of the model.

Amounts of N added in the rice–wheat system of the entire IGP through fertilizer, manure, and fixation (which includes N inputs through atmospheric deposition, biological fixation, and irrigation) were estimated to be 752,000, 167,000, and 243,000 t, respectively (Table 7). A similar amount of N input through fertilizer and manure has been reported by the Fertilizer Association of India (2003). Total N output was 1,515 Mt, out of which plant uptake accounted for 1,333 Mt. Losses of N were estimated to be 182,000 t. Ammonia volatilization, leaching, and denitrification accounted for 46, 38, and 16% of the total loss, respectively. About 20% of N applied through fertilizer and manure was lost from the system.

The relative proportions of different inputs and outputs in different states are presented in Table 7, which shows that fertilizer was the major input and plant uptake the major output of N. Uttar Pradesh accounted for 38 and 40%, followed by Punjab, which accounted for 34 and 28% of total inputs and outputs, respectively. The other three states (Bihar, Haryana, and West Bengal) together accounted for 28 and 31% of total inputs and outputs, respectively. All the states had a negative N balance, ranging from 5000 Mg in West Bengal to 174,000 Mg in Uttar Pradesh. The largest negative balance in Uttar Pradesh was due to a large N output relative to inputs and a large geographic area under the rice–wheat system in this state.

**CONCLUSIONS**

The DNDC model was generally able to capture the major effects of N and water on rice and wheat crop performance and balances of N in the rice–wheat systems of the IGP. The study showed that almost 30.4% of applied N was lost from the system and NH\(_3\) volatilization was the major loss mechanism, followed by leaching and denitrification. The simulated balance of N was negative in all the states. This shows the vulnerability of the system and calls for improved N management to stop the depletion of soil N. This is particularly true for the states of Bihar and Uttar Pradesh, where the depletion of soil N is the largest and immediate attention needs to be paid to minimize this depletion. The application of a higher amount of chemical N, substitution of a part of chemical N by organic N, and use of better management techniques to increase N use efficiency have been found to reduce the depletion and improve soil N status; however, higher fertilizer N use leads to more losses of N, which may cause environmental pollution. New tools for fertilizer management are therefore needed to reconcile the legitimate aims of improving N management and reducing losses and optimizing N application (Ladha et al., 2005). The analysis suggests that models such as the DNDC could be applied for studying N-related issues in the rice–wheat cropping systems of India and would be very useful to accelerate the application of available knowledge at field, farm, and regional levels for quantifying N losses and optimizing N management. Planning and agricultural extension personnel can use this tool for optimizing fertilizer availability and distribution in the various states, while the farmers can use it for improved fertilizer management. The model can also be used as a regulatory tool to make projections of future outcomes of fertilizer management scenarios with respect to key environmental areas such as NO\(_3\) leaching and environmental pollution.

**ACKNOWLEDGMENTS**

We acknowledge the International Atomic Energy Agency for supporting this study; H. Pathak is thankful to the Alexander von Humboldt Foundation, Germany, for providing a fellowship and Institut fur Meteorologie und Klimaforschung, Garmisch-Partenkirchen, Germany, for providing facilities to carry out the work; C. Li’s study was supported by the NASA Terrestrial Ecology Program through project TE/02-0018.
